Electronic structure of molecules

N nature molecules can found in a myriad of different shapes. Some like carbon dioxide are one-dimensional or linear, others like methane have a shape that expands in the three directions of the space—they have a three-dimensional shape. The shape of molecules results from the chemical bonds connecting atoms in a molecule and from the existence of lone pairs of electrons. This chapter covers the analysis of the molecular shape and gains insight into advanced models of the chemical bond. After studying the ideas in this chapter you will be able to draw the connections between the atoms of a molecule and to draft Lewis structures used as graphical representations of the molecular bonds. At the end of the chapter, we will address the idea of molecular polarity, which results from the distribution of charge in a molecule. Polarity will understand the reasons why you use soap to get rid of oil while doing dished.

1.1 Electron-dot structures of atoms

Atoms are made of protons, neutrons, and electrons. Electrons—in particular valence electrons—are responsible for the main chemical properties of an atom. These electrons are tied weakly to the nucleus in comparison with the core electrons and hence they can be exchanged easily with other atoms. Atoms in a molecule, with a few exceptions such as the hydrogen case, will tend to be surrounded by eight electrons so that its electron configuration resembles a noble gas. This is known as the octet rule (the duet rule in the case of hydrogen), and this rule is responsible for the common negative charge of F and the positive charge of Na: F ($[He]2s^22p^5$) can easily receive an extra electron producing ionic F⁻ ($[He]2s^22p^6$ =[Ne]) and atomic Na ($[Ne]3s^1$) can lose an electron producing ionic Na⁺ ($[He]2s^22p^6$ = [Ne]). The electron-dot structure of an atom or a molecule is a visual representation of the electronic arrangement in an atom or a molecule.

Valence electrons The electrons of an atom can be divided in core electrons and valence electrons. The valence electrons of an atom are involved in chemical bonds as they are less bonded to the nucleus. The number of valence electrons in an atoms is the same as the group number. As an example, hydrogen H belong to the group IA and hence has one valence electrons. Similarly, oxygen O belongs to the group VIA and therefore it has six valence electrons.

Sample Problem 1

Indicate the number of valence electrons for the following atoms: N, O, C and S.

SOLUTION

Discussion: oil spills on your shirt during a dinner. List three chemicals than can remove the stain

Nitrogen is in group VA and hence it has five valence electrons (5e⁻). Oxygen belongs to the group VIA and C belong to IVA, hence they have

STUDY CHECK

Indicate the number of valence electrons for the following atoms: Cl and B.

The octet rule Atoms gain or lose electrons when they combine to form molecules. This electron exchange is the driving force that drives the formation of molecules from single atoms. The octet rule claims that each atom in a molecule is normally surrounded by eight (octet) electrons. There are two important exceptions to this rule as H is only surrounded by two electrons (this is called the duet rule), and B by six.

Electron-dot structure of an atom In order to write the electron-dot structure of an atom, you just need to write down the symbol of the atom surrounded by the number of valence electrons located in the four directions of the space: top, bottom, right and left. In order to place the electrons, you start in any of the directions and fill one electron at a time. For example, for the case of three electrons we would have: 'B'. After the four direction has been filled, you need to start pairing the electrons. For example, for the case of five electrons we would have: 'P: Another example, oxygen has six valence electrons and hence, the electron-dot structure would be 'P: Similarly, for the case of fluorine the the electron-dot structure would be 'P: In the case of an ion, you need to add (if its an anion) or subtract (if its a cation) electrons, and for example the electron-dot structure of O²⁻ is : O:2-

Sample Problem 2

50

Write down the electron-dot structure for the following atoms: N, C and Cl⁻. **SOLUTION**

N has five valence electrons, whereas C has four. Hence the electron-dot for both will be: $\dot{\dot{N}}$ and $\dot{\dot{C}}$. Cl⁻ has eight valence electrons, that is seven plus one, and hence its electron-dot structure will be $\dot{\dot{C}}$!:-.

STUDY CHECK

Write down the electron-dot structure for N³-

Electron-dot structure of diatomic molecules. This section will address how to build up electron-dot structures of diatomic molecules. These would be the most simple electron-dot structures of molecules that you will see. The first step is (a) to set up the atoms in the molecule in the form of a line. After that, (b) you need to count the total number of valence electrons in the molecule by adding the valence electrons of each atom (remember the number of valence electrons corresponds to the group number in the A notation, O is 6 as its group is VIA). (c) compute the pairs of electrons—the total number of valence electrons divided by two; pairs of electrons are represented by lines (d) you need to start distributing the pairs in the molecule in a very specific way: first connecting the atoms among themselves, and after placing the remaining pairs surrounding the atoms. Overall, each atom should be surrounded by four pairs with the exception of H and B.

Construct the electron-dot structure of HCl.

SOLUTION

- 1 Step one: we first arrange the atoms in the molecule as H Cl.
- 2 Step two: now we count the number of valence electrons: H(1) and Cl(7) that gives a total of eight electrons.
- 3 Step three: let us count the pairs of electrons; we have eight electrons and that is four pairs.
- 4 Step four: now we distribute the pair on each atoms knowing that each atom has to have four pairs with the exception of hydrogen that can only be surrounded by one pair. H: Cl:, using lines instead of pairs (this is not necessary but makes the electron-dot structure look better) we obtain $H - \overline{Cl}$.

STUDY CHECK

Construct the electron-dot structure of HF.

Electron-dot structure of general molecules Now we will address how to build up electron-dot structures of more complex molecules. The first step is (a) to arrange the atoms in the molecule, in the form of a central atom and the remaining atoms around it; the central atom is the one with a lower index in the molecule (e.g. in H₂O is O or in NH₃ is N). After that, (b) you need to count the total number of valence electrons in the molecule, by adding the valence electrons of each atoms. Then you (c) calculate the pairs of electrons-the total number of valence electrons divided by two; pairs of electrons are represented by lines. In the following (d) you need to start distributing the pairs in the molecule in a very specific way (this is the key to building good electron-dot structures): first connecting the surrounding atoms to the central atom, after placing pairs on top of the surrounding atoms and finally by placing the remaining pairs in the central atom. Each atom should be surrounded by four pairs (this is the octet rule) with the exception of H and B as they do not follow the octet rule. When you have the final electron-dot structure, the pairs of electrons (or lines) that connect two atoms are called *bonds*, whereas the pairs not involved in an connection are called *lone pairs*. A very important note is that, at this point, is not that important the atom arrangement (if the molecule looks like a line, a triangle or so) as long as the connectivity (which atom goes in the center and in the surroundings) is correct.

Construct the electron-dot structure of H₂O indicating the number of bonds and lone pairs.

SOLUTION

- 1 Step one: we first arrange the atoms in the molecule as H O H. The central atom is O as oxygen has the lower index in the H2O molecule-the index for O is one and the index for H is two.
- 2 Step two: now we count the total number of valence electrons, including all atoms: 2xH(1) and O(6) that gives a total of eight electrons.

- 3 Step three: let us count the pairs of electrons; we have eight electrons and that is four pairs.
- 4 **Step four:** now we distribute the pair on each atoms knowing that each atom has to have four pairs with the exception of hydrogen that can only be surrounded by one pair. H: \ddot{Q} :H: and using lines instead of pairs (this is not necessary but makes the electron-dot structure look better) we obtain $H \overline{Q} H$. The molecule has two bonds, each one connecting and H to the oxygen atom and two lone pairs located on the oxygen atom.

105

110

Construct the electron-dot structure of NH₃ indicating the number of bonds and lone pairs.

Atomic charges in a molecule In order to build up the electron-dot structures of a molecule you needs to count the overall number of valence electrons of the molecule given that each atom brings a different number of valence electrons. For example, 2 H atoms brings one electron each, whereas O brings two electrons that gives a total of six electrons for water. When you arrange the electron pairs in the molecule, each atoms should be surrounded by the number of electrons that they bring. For example, in the electron-dot structure below

the central atom, nitrogen, has a five valence electrons. After counting the electrons surrounding nitrogen–remember in a bond each atom shared an electron and hence each line around an atom counts as one electron–we find that this atoms is surrounded by five electrons. As the number of valence electrons brought to the molecule is the same as the number of electrons surrounding the atom, we say the atomic charge of this atom is zero (Q=0). Hence, the atoms is neutral. In this next example,

the central atom, nitrogen, still has a five valence electrons. After counting the electrons surrounding nitrogen, this time we find that this atoms is surrounded by four electrons, less than the number of electrons originally brought to the molecule. We conclude that the atoms has positive charge. In particular, the effective atomic charge of nitrogen in this molecule is the number of valence electrons menus the number of surrounding electrons. In this case, the atomic charge is Q=+1. In this last example,

$$H \stackrel{\bullet \bullet}{\longleftarrow} H$$

The number of electrons surrounding nitrogen is six electrons, more than the number of electrons originally brought to the molecule. We conclude that the atoms has negative charge, and the effective atomic charge of nitrogen is Q=-1. In all the molecules above, hydrogen remains neutral and hence the atomic charge of nitrogen corresponds to the molecular charge of the molecule. We can hence summarize the three scenarios

indicated, as we have a neutral molecule on the center, a positive molecule on the right and a negative molecule on the left.

$$\begin{bmatrix} H - \ddot{N} - H \end{bmatrix} - H - \ddot{N} - H \begin{bmatrix} H - \ddot{N} - H \end{bmatrix}^{+}$$

Sample Problem 5

Indicate the atomic charges of the blue highlighted atom

$$H - \overline{C} - H$$

SOLUTION

The carbon atoms brings four electrons and in the molecule it is surrounded by eight electrons, five of which belongs to it. Hence the charge of C is -1; this means that carbon has one extra electron. Each hydrogen brings one electron and in the molecule each hydrogen has one electron (they share two electrons with C, one for C and one for H). The final lewis structure with the local charge of carbon can be indicated as:

$$\begin{bmatrix} H - \overline{C} - H \\ H \end{bmatrix}^{-}$$

Multiple bonds Often times you are going to encounter electron-dot structures like the ones below

$$:$$
 N \equiv N: and $:$ O $=$ O $:$

in which the atoms are connected by means of multiple bonds, double or triple bond. Multiple bonds are formed while constructing electron-dot structures in order to minimize large atomic charges while preserving the octet rule. Look for example the lewis structure for the HCN molecule. The Lewis structure on the left has a positive center and a negative center. On this structure, carbon do not follow the octet rule and neither does nitrogen. We can minimize the large atomic charges while enforcing the octet rule by moving lone pairs from the atoms into the bond. For example, if we move one of the lone pairs of nitrogen into the C-N bond we have the Lewis structure in the center. In this structure above, even when the charges are now low, still carbon and nitrogen do not follow the octet rule as they are not surrounded by four pairs of electrons. We can solve this problems by moving one more time a lone pair from N to the C-N bond forming the Lewis structure on the right, the most stable structure as the atomic charges are small and the octet rule is preserved.

$$H - C - N$$
: \longleftrightarrow $H - C = N$: \longleftrightarrow $H - C \equiv N$:

130

135

As you can see in this example, multiple bonds arise in Lewis structures to minimize large atomic charges. All the structures above are a set of different Lewis structures of the same molecule, each with a different stability. These structure are referred to as resonant structures.

Sample Problem 6

Construct the electron-dot structure of O_2 .

SOLUTION

- 1 Step one: we first arrange the atoms in the molecule as O O.
- 2 Step two: now we count the total number of valence electrons, including all atoms: 2xO(6) that gives a total of twelve electrons.
- 3 **Step three:** let us count the pairs of electrons; we have twelve electrons and that is six pairs.
- 4 **Step four:** now we distribute the pairs, fist connecting the atoms O O (we have five extra pairs to distribute at this point).
- 5 **Step five:** we place the remaining pairs on top of the oxygen atoms $|\overline{Q} O\rangle$
- 6 Step six: now we calculate the charge on each atom $|\overline{O} \ominus \oplus O\rangle$
- **Step seven:** in order to eliminate the charges we move lone pairs into the bond O = O Now the charges are zero and this is more important than imposing the octet rule.

STUDY CHECK

145

Construct the electron-dot structure of CO₂.

1.2 Molecular shape

Molecules are arrangements of atoms, and these arrangements can be presented in different form. Let us use as an example the H_2O molecule, which contains two hydrogen atoms and one oxygen. Knowing that both hydrogens are connected to oxygen by means of a covalent bond, one can envision several molecular geometries such as $H = \overline{\underline{O}} = H$ or maybe H . The goal of this section is to identify the geometry of a given molecule. In order to do this, the electron-dot structure of the molecule are the key.

ABE Molecular code If the molecule contains two atoms, there is only a possible geometry these two atoms can exhibit, and this is a linear arrangement. For the case of more complex molecules, in order to identify the geometry you need to figure out the ABE code of the molecule. In this code B refers to the number of atoms connected to the central atom in a molecule, and E is the number of lone pairs on the central atom. For example, the electron-dot $H - \overline{Q} - H$ structure has two bonds with the central atom B_2 and two lone pairs on top of the central atom E_2 and hence the ABE code of the molecule would be AB_2E_2 . Another example the ABE code for ammonia $H - \overline{N} - H$ would be AB_3E , as the molecule has three atoms connected to the central

nitrogen and and N has a single lone pair. You can find a list of the equivalence between ABE codes and the molecular geometry in Table ??. In order to predict the geometry of a molecule, once you have the ABE code, Table ?? will give you the geometry. For example, an AB₂ molecule will be linear, whereas an AB₂E₂ is bent. The bond angles are also indicated in the table, and for example a CO₂ molecule, which will be linear will have a 180° angle. This means both C-O bonds will form a line.

Sample Problem 7

Identify the geometry of the following molecules: BF₃ and SO₂.

SOLUTION

We need first the electron-dot structure of both molecules. For BF_3 $|\overline{F}-B-\overline{F}|$ The code of this molecule is AB_3 and hence its geometry would be trigonal planar. The correct way to draw the molecule respecting its geometry would be: $B-\overline{F}|$. The electron-dot structure for sulfur dioxide–remember this is |F| covalent molecule–is $|Q=\overline{S}=Q|$ and its class is AB_2E . Hence the molecular geometry is linear.

STUDY CHECK

Identify and draw the geometry of methane (CH₄).

Table 1.1 Molecular geometries

165

 $|\overline{\mathbf{F}}|$

1.3 Polarity of molecules

This section deals with bond and molecule polarity. A chemical bond will be polar or nonpolar depending on the tendency of the atoms in a bond to attract the electrons the bond. Polar bonds results in the existence of a permanent dipole moment that makes a molecule polar. Polar molecules can interact with polar molecules and mix.

Bond polarity Let us compare two different molecules: H2 and HCl. We say H2

175

180

185

190

is a non-polar molecule. The reason for this is that each atom in the covalent H-H bond equally share the electrons. Differently, HCl is a polar molecule, as H is an electropositive atom and Cl is electronegative. That implies that in the H-Cl covalent bond each atoms shares the electrons in the bond differently. H will be less prone to attract the electrons and Cl would tend to attract the bond electrons more than H. The result would be that the electrons in the bond would belong more to Cl than to H. Another consequence is that the molecule would have a permanent dipole–a permanent charge distribution–result of a uneven charge distribution in the chemical bond. We represent excess of charge as on Cl as $Cl^{\delta-}$ and electron deficiency in H as $H^{\delta+}$. The polarity of the bond is represented as:

Polarity of diatomic molecules Molecules can either be polar or non-polar. The polarity of diatomic molecules only depends on the nature of the atoms that forms the molecule. If the atoms in the molecule are the same (e.g. H₂ or O₂), then the molecule would be non-polar. If the atoms are different then the molecule would be polar. Examples are H₂ a nonpolar molecule and HCl or HBr, both polar molecules. You can apply the same concept to a bond inside a molecule. The C-O bond in a CO₂ molecule is a polar covalent bond, as C and O have different electronegativities.

Water (H_2O) is a polar molecule. The ABE type of water of AB_2E_2 and hence its geometry is bent. That means both H-O bonds, which are polar, do not compensate with each other. Hence, the molecule will have a dipole moment and hence will be polar. Methanol (CH₃OH) is a polar molecule as well. The central atom of the molecule (C) is connected to three hydrogens and a OH group. Hence this will be a polar molecule as one of the atoms attached to carbon is different. Both molecules, water and methanol, will mix as they have the same polarity. Methane (CH₄) is a nonpolar molecule, as the four polar C-H bonds compensate each other. Similarly, CCl₄, tetrachloro methene, is another nonpolar molecule, for the same reason. Both molecules, CH₄ and CCl₄ will mix together. As a general rule: molecules with the same polarity (polar-polar or nonpolar-nonpolar) will mix.

Polarity of larger molecules The polarity of larger molecules would depend on the molecular geometry. Let us analyze the case of CO_2 . Each of the C-O bonds on the molecule are polar bonds. However, CO_2 is a linear molecule O = C = O and the polarity of each C-O bonds compensate so that at the end the molecule is polar. For the O_2 case, again, the H-O bond is polar. However, the molecule is bent and looks just like O_2 H. Both H-O bonds do not compensate as they point in different direction and the directions do not cancel out what makes the water molecule to be a polar molecule.

Sample Problem

Identify the polar character (polar/nonpolar) of the following molecules: BF₃, SO₂ and CH₄.

SOLUTION

Let us analyze the geometries of the three molecules:

The bonds on SO₂ do not cancel out, as they do not point in opposite directions. Hence this molecule is polar. On the other hand, the bonds on methane and BF3 cancel each other out and hence even when the C-H and B-F bonds is polar, these two molecules would be non-polar.

STUDY CHECK

Identify the polar character (polar/nonpolar) of the following molecules: O2 and NH₃.

Polarity and mixing When you mix two different liquids or even gases, polarity is the key for the mixing process. If the molecules have the same polar character they will be able to mix, whereas they will not mix when the polar character is different. This section will cover several examples of mixing an polarity.

Table 1.2 Equivalency between the ABE code and the orbital hybridization										
ABE Code	Electron Regions	Hybrid	Shape	Bond Angle						
AB ₂ , ABE	2	sp	A) 180°						
AB ₃ , AB ₂ E,ABE ₃	3	${ m sp}^2$	A 210	120°						
AB ₄ , AB ₃ E,AB ₂ E ₂ ,ABE ₃	4	sp ³	A) 109.5°						
AB ₅ , AB ₄ E,AB ₃ E ₂ ,AB ₂ E ₃	5	$\mathrm{sp}^3 d$	A	90° and 120°						

Molecules with the same polarity Water (H_2O) is a polar molecule. The ABE type of water of AB₂E₂ and hence its geometry is bent. That means both H-O bonds, which are polar, do not compensate with each other. Hence, the molecule will have a dipole moment and hence will be polar. Methanol (CH₃OH) is a polar molecule as well. The central atom of the molecule (C) is connected to three hydrogens and a OH group. Hence this will be a polar molecule as one of the atoms attached to carbon is different. Both molecules, water and methanol, will mix as they have the same polarity. Methane (CH₄) is a nonpolar molecule, as the four polar C-H bonds compensate each other. Similarly, CCl₄, tetrachloro methene, is another nonpolar molecule, for the same reason. Both molecules, CH₄ and CCl₄ will mix together. As a general rule: molecules with the same polarity (polar-polar or nonpolar-nonpolar) will mix.

Molecules with different polarity CCl₄ is a nonpolar molecule, and H₂O is a polar molecule. As both have different polar character they will not mix together. If you mix water and CCl₄, tow phases will remain instead of a single mixed liquid phase. As a general rule: molecules with different polarity (polar-nonpolar) will not mix. Another example will be water and oil. Water is polar, and oil is a nonpolar molecule. As a consequence these two molecules will not mix together. Soap has a polar and non-polar part. In order to remove oil from water, soap helps mixing both polar water and nonpolar oil.

1.4 Hybrid orbitals

The molecular orbital theory is the most advanced bonding theory able to describe bond energies and bond lengths. Atomic orbitals are waves. When combining two waves one can obtain two possible results: a constructive combination and destructive combination. The molecular orbital theory assumes that atomic orbitals combine to form molecular orbitals. For every two atomic orbitals you can obtain two possible molecular orbitals: one is called bonding orbital, result from the constructive combination, and an other one called antibonding orbital, resulting from the destructive combination. In this section we will learn how to interpret molecular orbital diagrams.

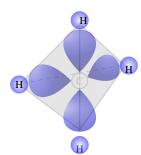

From ABE code to hybridization In order to obtain the hybridization of an atomic center in a molecule we just need the ABE code and Table ??. For example, if the code of a molecule is AB₄, the hybridization of the molecule will be sp^3 . Similarly, if the class is AB₃ the hybridization will be sp^2 and in this case an empty p orbital will remain in the bond–mind there are three different p orbitals: p_x , p_y and p_z . Another example, would be a molecule with class AB. In this case, the hybridization will be sp and two empty p orbital will remain in the bond. A final example would be a molecule with class AB₄E. This time, the hybridization would be sp^3d^2 . Mind that in general the number of hybrid orbitals correspond to adding the E and B from the class. For example, AB₄E₂, we have two E and four B with a total of six orbitals, hence we will need a s, three p's and two d's.

Sample Problem 9

Given the following Lewis structures, identify the hybridization of the central atom:

SOLUTION

In order to identify the hybrid character of the central atom, we first need

215

220

230

240

245

to obtain the ABE code. For BF₃ the class is AB₃, for SO₂ is AB₂E and finally for CH₄ is AB₄. The number of electron regions for BF₃ is three. Therefore we would need three hybrid orbitals: sp2. An empty p orbital will remain unused in the bond. For SO₂ we need three electron regions and hence the hybridization of the central atom will also be sp2. For the case of methane, the hybridization will be sp3, as the molecule has four electron regions.

STUDY CHECK

Identify the hybridization of the central atom for the following molecules: O₂ and NH₃.

1.5 Molecular orbital theory

Molecules are arrangements of atoms, and these arrangements can be presented in different form. Let us use as an example the H_2O molecule, which contains two hydrogen atoms and one oxygen. Knowing that both hydrogens are connected to oxygen by means of a covalent bond, one can envision several molecular geometries such as $H - \overline{Q} - H$ or maybe H. The goal of this section is to identify the geometry of a given molecule. In order to do this, the electron-dot structure of the molecule are the key.

Bonding and antibonding orbitals Atomic orbitals (AOs) combine to produce molecular orbitals (MOs). The combination of two atomic orbitals results in two new molecular orbitals: a bonding orbital and a antibonding orbital. Bonding MOs are more stable than the corresponding atomic orbitals. Antibonding MOs are less stable—they have a higher more positive energy—than the corresponding AOs. Antibonding orbitals are normally labeled with a * sign. Let us analyze both combinations of a 1s orbital. We can add both 1s orbital and the result is a bonding orbital, or we can substract both 1s orbitals and the result is an antibonding orbital, as the electron density cancels.

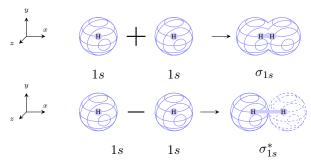

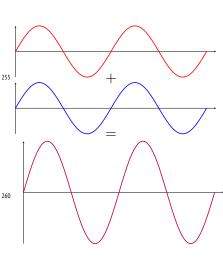

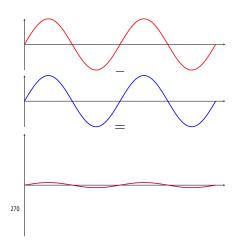

Figure 1.3 Bonding and antibonding σ orbitals resulting of combining two 1s atomic orbitals of Hydrogen.

Sigma and pi orbitals Let's analyze now the mixing of two $2p_x$ orbitals of two oxygen atoms in order to make an O_2 molecule. Mind that p orbitals look like dumbbells and each side of the dumbbell is called lobe. In the p_x orbital the positive lobe is in the right side and the negative love on the left side. When combining both $2p_x$ if we add both orbitals we obtain a bonding orbital and if we subtract them we obtain an antibonding orbital. Both of these orbitals are called σ orbitals, as the lobes of

the orbitals mixing go though the axes of the molecule being formed—the molecule is located in the X axis. Differently, if we combine two $2p_y$ orbitals we will obtain two π orbitals, as the lobes of the molecular orbital is perpendicular the axes of the molecule being formed The first orbital is bonding as both lobes overlap constructively, whereas the second orbital is antibonding as both lobes cancel out.

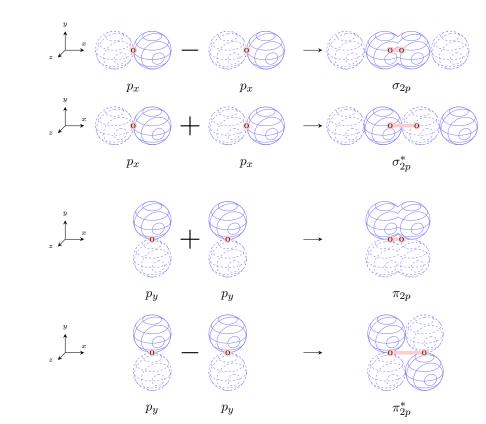

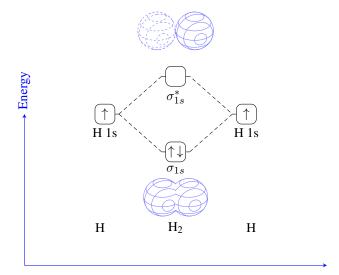

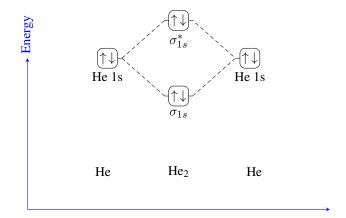

Figure 1.4 (Top) Bonding and antibonding σ orbitals resulting of combining two $2p_x$ atomic orbitals of Oxygen. (Bottom) Bonding and antibonding π orbitals resulting of combining two 2p atomic orbitals of Oxygen.

The case of molecular hydrogen Let us analyze the case of the formation of the H_2 molecule from two Hydrogen atoms. Each H atom has one 1s orbital. Therefore, according to the Molecular orbital theory, both orbitals will combine to produce two MO's. When you combine s atomic orbitals, the resulting MOs are always sigma. Sigma refers to the symmetry of the orbital. Therefore, the resulting MOs will be: σ_{1s} and σ_{1s}^* . Each AO contains one electron, hence the set of MO's will also contain two electrons that will occupy the most stable σ_{1s} . The resulting MO diagram is below. In this diagram, the atomic orbitals of H are on the left and right, whereas the MO's re in the center. We can also give the MO configuration as: $H_2 = \sigma_{1s}^2$. The hydrogen molecule is more stable than the separate hydrogen atoms. Why is that? the molecular orbitals of the molecule are lower in energy than the atomic orbitals of the hydrogen atoms. This means, the have more energy—as energy is negative that also means they are more stables. That is the reason why the hydrogen molecule is a stable existing molecule and takes energy to break down this molecule into atoms.

315

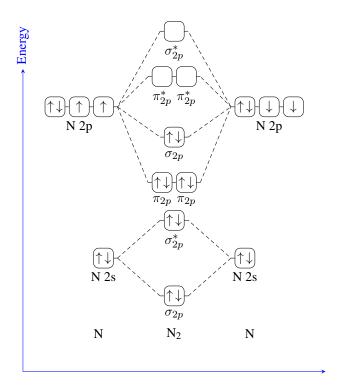

The case of molecular helium Let us analyze the case of the formation of the hypothetical Ne₂ molecule from two He atoms. Each He atom has one 1s orbital with two electrons. Therefore, according to the Molecular orbital theory, both orbitals will combine to produce two MO's with a total of four electrons. The resulting MOs will be as well: σ_{1s} and σ_{1s}^* . This time, MO configuration is: $\text{He}_2 = \sigma_{1s}^2 \sigma_{1s}^{*2}$. In general antibonding orbitals are not stable. In the He molecule we stabilize the molecule by forming two σ_{1s}^2 orbitals, but we also destabilize the molecule by forming σ_{1s}^{*2} . Hence the He₂ molecule will not be stable in compared to the atoms:

From MO diagram to MO configuration Obtaining a MO diagram is not obvious, and these diagrams can only be obtained after very complicated quantum mechanics simulations. However, after the MO diagram is given, one can obtain the MO configuration. From this configuration we can calculate two main properties: the bond order–related to the length of the molecule—and the magnetic character of the molecule. Let us use the case of N₂: In this diagram, the lower MO's are the most stables and should be filled first. The higher MO are less stable and they are listed in the right side of the MO configuration. For example, the MO configuration of N₂ would be:

$$N_2 = \sigma_{2s}^2 \sigma_{2s}^{*2} \pi_{2p}^4 \sigma_{2p}^2$$

Bond order of a MO configuration Lets go back to the MO configuration for N₂. In this configuration we have some of the electrons occupying bonding MO and other occupying antibondoing MO's. The bond order is just the number of bonding electrons—the number of electrons occupying bonding MO's—minus the number of antibonding electrons—the number of electrons occupying antibonding MO's—divided by two. The formula is:

$$\left(BO = \frac{(n-n^*)}{2}\right)$$
 Bond Order

where:

n is the number of electrons occupying bonding MO's n^* is the number of electrons occupying antibonding MO's

The bond order is related to the stability of the molecule and to the length of its chemical bond. The larger the bond order the most stable is the molecule as more electrons occupy bonding orbitals. The larger the bond order the smaller the chemical bond, and the atoms are more loose.

Sample Problem 10

Given the following MO configurations: (a) $\sigma_{2s}^2 \sigma_{2s}^{*2} \pi_{2p}^4 \sigma_{2p}^1$ and (b) $\sigma_{2s}^2 \sigma_{2s}^{*2} \pi_{2p}^4 \sigma_{2p}^2 \pi_{2p}^{*3}$. Calculate the bond order and compare the length of the chemical bond of both molecules.

SOLUTION

The bond order is the number of bonding electrons minus the number of antibonding electrons divided by two. For the first example, we have seven bonding electrons and tow antibonding. Hence the bond order will be 2.5. For the second example, we have eight bonding electrons and five antibonding. Hence the bond order will be 1.5. The larger the BO the smaller the bond, hence the second molecule has a smaller bond.

STUDY CHECK

Calculate the bond order for $\sigma_{2s}^2 \sigma_{2s}^{*2} \pi_{2n}^4 \sigma_{2n}^2$.

Paramagnetism and diamagnetism One of the uses of the MO configuration is to predict the magnetic character (magnetic or non-magnetic) of a molecule. By reading the MO configuration of a molecule, we can also predict its magnetic character and hence estimate its magnetic properties. Paramagnetic molecules (normally referred to as magnetic) are attracted by magnetic fields, whereas diamagnetic molecules (normally referred to as non-magnetic) are repelled by magnetic fields. The magnetic character results from the presence of unpaired electrons in the MO configuration. For example: $\sigma_{2s}^2\sigma_{2s}^{*1}$ is a paramagnetic (magnetic) molecule as we have one unpaired electron in the σ_{2s}^* orbital. In contrast, $\sigma_{2s}^2\sigma_{2s}^{*2}$ is a diamagnetic (non-magnetic) molecule, as it has no unpaired electrons.

Sample Problem 11

Given the following MO configurations, predict the magnetic character: (a) $\sigma_{2s}^2 \sigma_{2s}^{*2} \pi_{2p}^4 \sigma_{2p}^1$ and (b) $\sigma_{2s}^2 \sigma_{2s}^{*2} \pi_{2p}^4 \sigma_{2p}^2 \pi_{2p}^{*3}$.

SOLUTION

The first example has an unpaired σ electron and hence it is paramagnetic. The second base also has a single unpaired electron, this time in the π_{2p}^* orbital. Mind π orbitals have capacity of four and hence can place two separate pairs of electrons.

STUDY CHECK

Given the following MO configurations, predict the magnetic character: (a) $\sigma_{2s}^2 \sigma_{2s}^{*2} \pi_{2p}^4 \sigma_{2p}^2$ and (b) $\sigma_{2s}^2 \sigma_{2s}^{*2} \pi_{2p}^4 \sigma_{2p}^2 \pi_{2p}^{*2}$.

ELECTRON-DOT STRUCTURES OF MOLECULES

1.1 Indicate the charge of the atom marked blue in the following electron-dot structure:

(a)
$$\begin{bmatrix} H - \overline{C} - H \end{bmatrix}$$

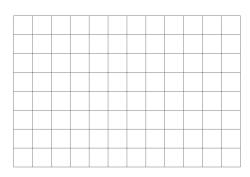

(b)
$$\begin{bmatrix} H - \overline{O} - H \\ H \end{bmatrix}$$

1.2 Indicate the charge of the atom marked blue in the following electron-dot structure:

(a)
$$\begin{bmatrix} H \\ H - N - H \\ I \\ H \end{bmatrix}$$

(a)
$$\begin{bmatrix} H \\ H - N - H \\ I \\ H \end{bmatrix}$$
 (b)
$$\begin{bmatrix} H \\ H - C - \overline{O} \\ I \\ H \end{bmatrix}$$

1.3 Draw the electron-dot structure of: (a) BH₃ (b) CH₄

1.4 Draw the electron-dot structure of: (a) NH₄⁺ (b) H₃O⁺

1.5 The electron-dot structure of HI is:

- (a) $|H \overline{I}|$
- (d) $\overline{H} \overline{I}$
- (b) |H I|
- (c) |H I|
- (e) $H \overline{I}$

1.6 Indicate the charge of the atom marked blue in the following electron-dot structure:

(a)
$$\begin{bmatrix} H - \overline{C} - H \\ H \end{bmatrix}$$

(b)
$$\begin{bmatrix} H - \overline{O} - H \\ \downarrow \\ H \end{bmatrix}$$

1.7 Indicate the charge of the atom marked blue in the following electron-dot structure:

(a)
$$\begin{bmatrix} H \\ H \\ H - N - H \\ H \end{bmatrix}$$

(b)
$$\begin{bmatrix} H \\ H - \overline{C} - \overline{\underline{O}} \\ H \end{bmatrix}$$

MOLECULAR SHAPE

1.8 Identify the molecular shape of the molecules: NH₃

1.9 Identify the molecular shape of the molecules: (a) H₂ (b) BeCl₂ BF₃

POLARITY

1.10 Indicate the polarity or non-polarity for the following molecules: (a) H₂O (b) HCl (c) H₂

1.11 Indicate the polarity or non-polarity for the following molecules: (a) NH₃ (b) CO₂

HYBRID ORBITALS

1.12 Indicate the hybridization of: (a) NH₃ (b) CH₄ (c) H₂O

1.13 Indicate the hybridization of: (a) NH₃ (b) CH₄ (c) H₂O

MOLECULAR ORBITAL THEORY

1.14 Using the MO order provided below

$$\sigma_{2s}\sigma_{2s}^*\pi_{2p}\sigma_{2p}\pi_{2p}^*\sigma_{2p}^*$$

obtain the MO configuration for: (a) B2 (b) C2

1.15 Using the MO order provided below

$$\sigma_{2s}\sigma_{2s}^*\pi_{2p}\sigma_{2p}\pi_{2p}^*\sigma_{2p}^*$$

obtain the MO configuration for: (a) O₂ (b) F₂⁺

1.16 Indicate the magnetic (paramagnetic or diamagnegtic) configuration of the molecule with MO configuration: $\sigma_{2s}^2 \sigma_{2s}^{2*} \sigma_{2p}^2 \pi_{2p}^4 \pi_{2p}^{3*}$

Answers 1.1 (a) -2 (b) +1 1.3 (a) H - B - H (b) H - \overline{C} - H 1.5 H - $\overline{\underline{I}}$ 1.7 (a) +1 (b) -1 1.9 (a) H₂ (Linear) (b) BeCl₂ (Linear) BF₃ (Trigonal planar) 1.11 (a) NH₃ (b) CO₂ 1.13 (a) NH₃ (sp^3) (b) CH₄ (sp^3) (c) H₂O (sp^3)
